## General Description

The MAX3675 is a complete clock-recovery and dataretiming IC incorporating a limiting amplifier. It is intended for 622Mbps SDH/SONET applications and operates from a single +3.3 V supply.
The MAX3675 has two differential input amplifiers: one accepts PECL levels, while the other accepts small-signal analog levels. The analog inputs access the limiting amplifier stage, which provides both a received-signalstrength indicator (RSSI) and a programmable-threshold loss-of-power (LOP) monitor. Selecting the PECL amplifier disables the limiting amplifier, conserving power. A loss-of-lock (LOL) monitor is also incorporated as part of the fully integrated PLL.

## Applications

SDH/SONET Transmission Systems
SDH/SONET Access Nodes
Add/Drop Multiplexers
ATM Switches
Digital Cross-Connects

Features

- Single +3.3 V or +5.0 V Power Supply
- Complies with ANSI, ITU, and Bellcore SDH/SONET Specifications
- Low Power: 215mW at +3.3V
- Selectable Data Inputs, Differential PECL or Analog
- Received-Signal-Strength Indicator (RSSI)
- Loss-of-Power and Loss-of-Lock Monitors
- Differential PECL Clock and Data Outputs
- No External Reference Clock Required

Figure 1. Functional Diagram

## Detailed Description

Figure 1 shows the MAX3675's architecture. It consists of a limiting amplifier input stage followed by a fully integrated clock/data-recovery (CDR) block implemented with a PLL. The input stage is selectable between a limiting amplifier or a simple PECL input buffer. The limiting amplifier provides an LOP monitor and an RSSI. The PLL consists of a phase/frequency detector (PFD), a loop filter amplifier, and a voltage-controlled oscillator (VCO).

## Limiting Amplifier

The MAX3675's on-chip limiting amplifier accepts an input signal level from $3.0 \mathrm{mVp}-\mathrm{p}$ to $1.2 \mathrm{Vp}-\mathrm{p}$. The amplifier consists of a cascade of gain stages that include full-wave logarithmic detectors. The combined smallsignal gain is approximately 42 dB , and the -3 dB bandwidth is 800 MHz . Input-referred noise is less than $100 \mu \mathrm{~V}_{\text {RMS }}$, providing excellent sensitivity for smallamplitude data streams.

In addition to driving the CDR, the limiting amplifier provides both an RSSI output and an LOP monitor that allow the user to program the threshold voltage. The RSSI circuitry provides an output voltage that is linearly proportional to the input power (in decibels) detected between the ADI+ and ADI- input pins and is sensitive enough to reliably detect signals as small as $2 \mathrm{mVp}-\mathrm{p}$.
Input DC offset reduces the accuracy of the power detector; therefore, an integrated feedback loop is included that automatically nulls the input offset of the gain stage. The addition of this offset-correction loop requires that the input signal be AC-coupled when using the ADI+ and ADI- inputs.
Finally, for applications that do not require the limiting amplifier, selecting the digital inputs conserves power by turning off the postamplifier block.

Phase Detector
The phase detector produces a voltage proportional to the phase difference between the incoming data and

# 622Mbps, Low-Power, 3.3V Clock-Recovery and Data-Retiming IC with Limiting Amplifier 

the internal clock. Because of its feedback nature, the PLL drives the error voltage to zero, aligning the recovered clock to the incoming data. The external phase adjustment pins (PHADJ+, PHADJ-) allow the user to vary the internal phase alignment.

## Frequency Detector

A frequency detector incorporated into the PLL aids frequency acquisition during start-up conditions. The input data stream is sampled by quadrature components of the VCO clock, generating a difference frequency. Depending on the polarity of the difference frequency, the PFD drives the VCO so that the difference frequency is reduced to zero. Once frequency acquisition is obtained, the frequency detector returns to a neutral state.

Loop Filter and VCO The VCO is fully integrated, while the loop filter requires an external R-C network. This filter network determines the bandwidth and peaking of the second-order PLL.

## Design Procedure

## Received-Signal-Strength <br> Indicator (RSSI)

The RSSI output voltage is insensitive to temperature and supply fluctuations. The power detector functions as a broadband power meter that detects the total RMS power of all signals within the detector bandwidth (including input signal noise). The RSSI voltage varies linearly (in decibels) for inputs of $2 \mathrm{mVp}-\mathrm{p}$ to $50 \mathrm{mVp}-\mathrm{p}$. The slope over this input range is approximately 29mV/dB.

The high-speed RSSI signal is filtered to an RMS level with one external capacitor tied from CFILT to VCC. The impedance looking into CFILT is about $500 \Omega$ to VCC. As a result, the lower -3dB cutoff frequency is set by the following simple relationship:

$$
f_{\text {FILT }}=1 /\left[2 \pi(500) C_{F}\right]
$$

For 622Mbps applications, Maxim recommends a cutoff frequency of 6.8 kHz , which requires $\mathrm{CF}=47 \mathrm{nF}$. The RSSI output is designed to drive a minimum load resistance of $10 \mathrm{k} \Omega$ to ground and a maximum of 20 pF . Loads greater than 20pF must be buffered by a series resistance of $10 \mathrm{k} \Omega$ (i.e., voltmeter).

## Input Offset Correction

The on-chip limiting amplifier provides more than 42dB of gain. A low-frequency feedback loop is integrated into the MAX3675 to remove the input offset. DC-coupling to the ADI+ and ADI- inputs is not allowed, as this
would prevent the proper functioning of the DC offsetcorrection circuitry.
The differential input impedance ( $\mathrm{Z}_{\mathrm{I}}$ ) is approximately $2.5 \mathrm{k} \Omega$. The impedance between OLC+ and OLC- (ZOLC) is approximately $120 \mathrm{k} \Omega$. Take care when setting the combined low-frequency cutoff (fCUTOFF), due to the input DC-blocking capacitor (CIN) and the offset correction loop capacitor (COLC). See Table 1 for selecting the values of CIN and COLC.
These values ensure that the poles associated with CIN and Colc work together to provide a flat response at the lower -3dB corner frequency (no gain peaking).
CIN must be a low-TC, high-quality capacitor of type X7R or better in order to minimize fCUTOFF deviations. COLC must be a capacitor of type Z 5 U or better.

## Loss-of-Power (LOP) Monitor

A LOP monitor with a user-programmable threshold and a hysteresis comparator is also included with the limiting amplifier circuitry. Internally, one comparator input is tied to the RSSI output signal, and the other is tied to the threshold voltage (VTH), which is set externally and provides a trip point for the LOP indication. A low-voltage, low-drift op amp, referenced to an internal bandgap voltage ( 1.18 V ), is supplied for programming a supply independent threshold voltage. This op amp requires two external resistors to program the LOP trip point. $\mathrm{V}_{\text {TH }}$ is programmable from 1.18 V to 2.4 V using the equation:

$$
V_{T H}=1.18(1+R 2 / R 1)
$$

The op amp can source only $20 \mu \mathrm{~A}$ of current. Therefore, an R1 value greater than or equal to $100 \mathrm{k} \Omega$ is recommended for proper operation. The input bias current of the op amp at the INV pin is guaranteed to be less than

Table 1. Setting the Low-Frequency Cutoff

| $\mathbf{C}_{\text {IN }}$ | CoLc | COMBINED LOW <br> fcutorf (kHz) |
| :---: | :---: | :---: |
| $0.022 \mu \mathrm{~F}$ | $0.047 \mu \mathrm{~F}$ | 3.0 |
| $0.010 \mu \mathrm{~F}$ | $0.033 \mu \mathrm{~F}$ | 6.8 |
| 6800 pF | $0.022 \mu \mathrm{~F}$ | 10 |
| 4700 pF | $0.010 \mu \mathrm{~F}$ | 13.5 |
| 2200 pF | 4700 FF | 29 |
| 1000 pF | 3300 pF | 68 |
| 470 pF | 1000 pF | 135 |

| 220 pF | 470 pF | 290 |

# 622Mbps, Low-Power, 3.3V Clock-Recovery and Data-Retiming IC with Limiting Amplifier 

$\pm 100 \mathrm{nA}$. To set the threshold voltage externally (i.e., via a DAC control), completely disable the op amp by grounding the inverting terminal (INV). VTH then becomes high impedance and must be driven externally.
The comparator is configured with an active-high LOP output. An on-chip, $6 \mathrm{k} \Omega$ pull-up resistor is provided to reduce external part count.

## Setting the Loop Filter

The loop filter within the PLL consists of a transconductance amplifier and external filter elements $\mathrm{RF}_{\mathrm{F}}$ and $\mathrm{C}_{\mathrm{F}}$ (Figure 2). The closed-loop bandwidth of a PLL is approximated by:

$$
\mathrm{K}_{\mathrm{D}} \mathrm{~K}_{\mathrm{O}} \mathrm{Gm} \mathrm{R}_{\mathrm{F}}
$$

where $K_{D}$ is the gain of the phase detector, $\mathrm{K}_{\mathrm{O}}$ is the gain of the VCO, and Gm is the transconductance of the filter amplifier. For the MAX3675, an estimated value of $\mathrm{K}_{\mathrm{DKOGm}}$ is 7 k .

Figure 2. Loop Filter

Because the PLL is a second-order system, a zero in the open-loop gain is required for stability. This zero is set by the following equation:

$$
\omega_{z}=1 /\left(R_{F} C_{F}\right)
$$

where the recommended external value of $C F$ is $2.2 \mu \mathrm{~F}$.
Increasing the value of RF increases the PLL bandwidth (floOP). Increasing this bandwidth improves jitter tolerance and jitter-generation performance, but also reduces jitter-transfer performance. (Decreasing the bandwidth has the opposite effect.)
This type of PLL is a classical second-order system. Therefore, as $\mathrm{f}_{\mathrm{z}}$ (the frequency of the zero) approaches fLOOP, the jitter-transfer peaking increases. For an overdamped system ( $f_{z} / f$ LOOP $)<0.25$, the jitter peaking of a second-order system can be approximated by:

$$
\mathrm{Mp}=1-\left(\mathrm{f}_{\mathrm{z}} / \mathrm{fLOOP}\right)
$$

where Mp is the magnitude of the peaking. For ( $\mathrm{f}_{\mathrm{z}} / \mathrm{fLOOP}$ ) $<0.1$, this equation holds to within $10 \%$.
CF can be made smaller if meeting the jitter-transfer specifications is not a requirement. For example, setting $R_{F}$ to $300 \Omega$ and $C_{F}$ to $3.3 n F$ increases the loop bandwidth to approximately 2.2 MHz (Figure 3). Loop stability is ensured by maintaining a separation of $10 \times$ between fLOOP and $\mathrm{f}_{\mathrm{z}}$. Be careful when changing the value of RF. Lower values of RF are limited by the internal resistance of the IC, and upper values are limited by the internal high-frequency pole.
The MAX3675 is optimally designed to acquire lock and to provide a bit-error rate (BER) of less than $10^{-10}$ for long strings of consecutive zeros and ones. Using the recommended external component values of $R F=52.3 \Omega \pm 1 \%$

Figure 3. Loop-Filter Response

# 622Mbps, Low-Power, 3.3V Clock-Recovery and Data-Retiming IC with Limiting Amplifier 

and $C F=2.2 \mu \mathrm{~F} \pm 20 \%$, measured results show that the MAX3675 can tolerate 1000 consecutive ones or zeros. It is important to select a type of capacitor for CF that has a temperature stability of $\pm 10 \%$ or better. This ensures performance over the $-40^{\circ} \mathrm{C}$ to $+85^{\circ} \mathrm{C}$ temperature range.

## Lock Detect

The MAX3675's LOL monitor indicates when the PLL is locked. Under normal operation, the loop is locked and the $\overline{\mathrm{LOL}}$ output signal is high. When the MAX3675 loses lock, a fast negative-edge transition occurs on $\overline{\mathrm{LOL}}$. The output level remains at a low level (held by CLOL) until the loop reacquires lock (Figure 4).

## Input and Output Terminations

The MAX3675 digital data and clock I/Os (DDI+, DDI-, SDO+, SDO-, SCLK+, and SCLK-) are designed to interface with PECL signal levels. It is important to bias these ports appropriately. A circuit that provides a Thevenin equivalent of $50 \Omega$ to $V_{C C}-2 V$ should be used with fixed-impedance transmission lines for proper termination. Make sure that the differential outputs have balanced loads.

The digital data input signals (DDI+ and DDI-) are differential inputs to an emitter-coupled pair. As a result, the MAX3675 can accept differential input signals as low as 250 mV . These inputs can also be driven singleended by externally biasing DDI- to the center of the voltage swing.
The MAX3675's performance can be greatly affected by circuit board layout and design. Use good high-frequency design techniques, including minimizing ground inductance and using fixed-impedance transmission lines on the data and clock signals. Power-sup-

Figure 4. Loss-of-Lock Output
ply decoupling should be placed as close to VCC as possible. Take care to isolate the input from the output signals to reduce feedthrough.

## Applications Information

## Driving the Limiting Amplifier Single-Ended

There are three important requirements for driving the limiting amplifier from a single-ended source (Figure 5):

1) There must be no DC-coupling to the ADI+ and ADIinputs. DC levels at these inputs disrupt the offset-correction loop.
2) The terminating resistor $\mathrm{R}_{\mathrm{T}}(50 \Omega)$ must be referenced to the ADI- input to minimize common-mode coupling problems.
3) The low-frequency cutoff for the limiting amplifier is determined by either $\mathrm{CIN}_{\mathrm{IN}}$ and the $2.5 \mathrm{k} \Omega$ input impedance or $\mathrm{Cb}_{\mathrm{b}} / 2$ together with $\mathrm{R}_{\mathrm{T}}$. With $\mathrm{C}_{b}=0.22 \mu \mathrm{~F}$ and $\mathrm{RT}=50 \Omega$, the low-frequency cutoff is 29 kHz .

Figure 5. Single-Ended Input Termination

# 622Mbps, Low-Power, 3.3V Clock-Recovery and Data-Retiming IC with Limiting Amplifier 

## Reduced Power Consumption Without the Limiting Amplifier

The limiting amplifier is biased independently from the clock recovery circuitry. Grounding INSEL turns off the limiting amplifier and selects the PECL DDI inputs.

## Converting Average Optical Power to Signal Amplitude

Many of the MAX3675's specifications relate to inputsignal amplitude. When working with fiber optic receivers, the input is usually expressed in terms of average optical power and extinction ratio. The relations given in Table 2 and Figure 6 are helpful for converting optical power to input signal when designing with the MAX3675.
In an optical receiver, the input voltage to the limiting amplifier can be found by multiplying the relationship in Table 2 by the photodiode responsivity and transimpedance amplifier gain.

Optical Hysteresis
Power and hysteresis are often expressed in decibels. By definition, decibels are always 10log (power). At the inputs to the MAX3675 limiting amplifier, the power is $\mathrm{V}_{\mathrm{IN}}{ }^{2} / \mathrm{R}$. If a receiver's optical input power ( x ) increases by a factor of two, and the preamplifier is linear, then the voltage at the input to the MAX3675 also increases by a factor of two.
The optical power increase is $10 \log (2 x / x)=10 \log (2)=$ +3 dB .
At the MAX3675, the voltage increase is:

$$
10 \log \frac{\left(2 \mathrm{~V}_{I N}\right)^{2} / \mathrm{R}}{\mathrm{~V}_{I N}{ }^{2} / \mathrm{R}}=10 \log \left(2^{2}\right)=20 \log (2)=+6 \mathrm{~dB}
$$

Table 2. Optical-Power Relations*

| PARAMETER | SYMBOL | RELATION |
| :--- | :---: | :---: |
| Average <br> Power | PAVE | $\mathrm{P}_{\mathrm{AVE}}=(\mathrm{PO}+\mathrm{P} 1) / 2$ |
| Extinction <br> Ratio | $\mathrm{re}_{\mathrm{e}}$ | $\mathrm{r}_{\mathrm{e}}=\mathrm{P} 1 / \mathrm{PO}$ |
| Optical Power <br> of a "1" | P 1 | $\mathrm{P} 1=2 \mathrm{P}_{\mathrm{AVE}} \frac{\mathrm{r}_{\mathrm{e}}}{\mathrm{r}_{\mathrm{e}}+1}$ |
| Optical Power <br> of a "0" | $\mathrm{P0}$ | $\mathrm{P} 0=2 \mathrm{P}_{\mathrm{AVE}} /\left(\mathrm{r}_{\mathrm{e}}+1\right)$ |
| Signal <br> Amplitude | PIN | $\mathrm{P}_{\mathrm{IN}}=\mathrm{P} 1-\mathrm{PO}=2 \mathrm{P}_{\mathrm{AVE}} \frac{\left(\mathrm{r}_{\mathrm{e}}-1\right)}{\mathrm{r}_{\mathrm{e}}+1}$ |

[^0]In an optical receiver, the dB change at the MAX3675 always equals $2 x$ the optical dB change.
The MAX3675's typical voltage hysteresis is 3.0dB. This provides an optical hysteresis of 1.5 dB .

## Jitter in Optical Receivers

Timing jitter, edge speeds, aberrations, optical dispersion, and attenuation all impact the performance of high-speed clock recovery for SDH/SONET receivers (Figure 7). These effects decrease the time available for error-free data recovery by reducing the received "eye opening" of nonreturn-to-zero (NRZ) transmitted signals.

Figure 6. Optical Power Relations

Figure 7. Eye Diagram With and Without Timing Jitter

# 622Mbps, Low-Power, 3.3V Clock-Recovery and Data-Retiming IC with Limiting Amplifier 

Optical receivers, incorporating transimpedance preamplifiers and limiting postamplifiers, can significantly clean up the effects of dispersion and attenuation. In addition, these amplifiers can provide fast transitions with minimal aberrations to the subsequent CDR blocks. However, these stages also add distortions to the midpoint crossing, contributing to timing jitter. Timing jitter is one of the most critical technical issues to consider when developing optical receivers and CDR circuits.
A better understanding of the different sources of jitter helps in the design and application of optical receiver modules and integrated CDR solutions. SDH/SONET specifications are well defined regarding the amount of jitter tolerance allowed at the inputs of optical receivers, as well as jitter peaking requirements, but they do little to define the different sources of jitter. The jitter that must be tolerated at an optical receiver input involves three significant sources, all of which are present in varying degrees in typical receiver systems:

1) Random jitter (RJ)
2) Pattern-dependent jitter (PDJ)
3) Pulse-width distortion (PWD)

Random Jitter (RJ)
$R J$ is caused by random noise present during edge transitions (Figure 8). This random noise results in random midpoint crossings. All electrical systems generate some random noise; however, the faster the speed
of the transitions, the lower the effect of noise on random jitter. The following equation is a simple worstcase estimation of random jitter:

$$
\text { RJ (rms) }=\text { (rms noise) / (slew rate) }
$$

Pattern-Dependent Jitter (PDJ)
PDJ results from wide variations in the number of consecutive bits contained in NRZ data streams working against the bandwidth requirements of the receiver (Figure 9). The location of the lower -3dB cutoff frequency is important, and must be set to pass the low frequencies associated with long consecutive bit streams. AC-coupling is common in optical receiver design.
When using a limiting preamplifier with a highpass frequency response, select the input AC-coupling capacitor, CIN, to provide a low-frequency cutoff (fc) one decade lower than the preamplifier low-frequency cutoff. As a result, the PDJ is dominated by the lowfrequency cutoff of the preamplifier.
When using a preamplifier without a highpass response with the MAX3675, the following equation provides a good starting point for choosing CIN:

where $\mathrm{tL}=$ duration of the longest run of consecutive bits of the same value (seconds); PDJ = maximum

Figure 9. Pattern-Dependent Jitter Due to Low-Frequency Cutoff

allowable pattern-dependent jitter, peak-to-peak (seconds); and BW = typical system bandwidth, normally 0.6 to 1.0 times the data rate (Hertz). If the PDJ is still larger than desired, continue increasing the value of CIN. Note that to maintain stability when using the MAX3675 analog inputs (ADI+, ADI-), it is important to keep the low-frequency cutoff associated with Colc below the corner frequency associated with CIN (fC) (Table 1).
PDJ can also be present due to insufficient high-frequency bandwidth (Figure 10). If the amplifiers are not fast enough to allow for complete transitions during sin-gle-bit patterns, or if the amplifier does not allow adequate settling time, high-frequency PDJ can result.

Pulse-Width Distortion (PWD)
Finally, PWD occurs when the midpoint crossing of a $0-1$ transition and a 1-0 transition do not occur at the

Figure 10. Pattern-Dependent Jitter Due to High-Frequency Rolloff
same level (Figure 11). DC offsets and nonsymmetrical rising and falling edge speeds both contribute to PWD. For a 1-0 bit stream, calculate PWD as follows:

PWD $=[($ width of wider pulse $)$ (width of narrower pulse)] / 2

Phase Adjust
The internal clock and data alignment in the MAX3675 is well maintained close to the center of the data eye. Although not required, this sampling point can be shifted using the PHADJ inputs to optimize BER performance. The PHADJ inputs operate with differential input signals to approximately $\pm 1 \mathrm{~V}$. A simple resistordivider with a bypass capacitor is sufficient to set up these levels. When the PHADJ inputs are not used, they should be tied directly to VCC.
